

Now a camera that captures the action after it happens

With technology advancing in leaps and bounds, our memories could last forever. With all this in mind, Ben Bodley and Sam Lee have come out with meMINI, a wearable Wi-Fi-enabled camera with 'recall,' which helps users save film-worthy moments in high-definition video after they have already come and gone.

Ideally, the meMINI 'rewrites' a continuous loop of video, but will save the previous few minutes of footage whenever the user presses a button on it. Looping footage is captured every five seconds to five minutes. To permanently store the last recorded moment, users can press the recall button to transfer a file to a cloud-based storage or the camera's internal memory.

meMINI can loop video for three continuous hours on a full charge. It continuously records one several-minute stretch of footage after another, each one replacing the one that was recorded before it. In the meantime, if something noteworthy happens, the user can instruct it to save that one stretch of footage, and it is done. It also lets users share moments they have recorded via e-mail, social media or with the meMINI community.

First ever jellyfish aircraft

Scientists at the New York University's Applied Math Lab have developed the world's first jellyfish aircraft, which captures the exact motion of a jellyfish in water. Engineers across the globe have long marvelled at a jellyfish's simple, efficient motion and wanted to recreate the same in a drone.

This rare feat was achieved by using four petal-shaped wings made from over-the-counter components: light carbon-fibre ribs to hold the motor and provide the frames of the wings, which are covered by transpar-

ent Mylar film. Each petal measures 8 cm and is folded together to form a downward-facing cone. A tiny motor attached to the crankshaft pushes the wing outwards and downwards 20 times in a second, forcing air out via the bottom of the cone. The result is an ornithopter that is incredibly stable and does not require constant correction. If, however, it is knocked over, it stabilises by itself. Change in direction of motion is achieved by making one wing out of the four work harder than the others.

Smart contact lens to detect diabetes

Google, known for some of the best

innovations, has created a buzz again. It is the latest moonshot project, which might open some eyes to new possibilities, with the Internet giant coming up with the smart contact lens. However, it must be noted that the smart contact lens must not be confused with Google's soon-to-be consumer-friendly Glass.

The smart contact lens has been designed specifically for people diagnosed with diabetes, cited to afflict one in every 19 people worldwide, to measure glucose levels in tears. It hosts a tiny wireless chip and miniaturised glucose sensor, both of which are embedded between two layers of soft contact lens material.

The project's co-founders, Brian Otis and Babak Parviz, highlighted the motivations behind developing the same in an official blog post. "Glucose levels change frequently with normal activity such as exercising or eating or even sweat-
